Hepatitis A virus (HAV) infection is often asymptomatic or mildly symptomatic in pediatric population, the severity of the disease increases by age. Immune-mediated extrahepatic manifestations and hematologic complications are mainly reported in adults with acute and chronic hepatitis B and C. However, they are relatively rare in children with HAV infection. There are few available pediatric reports in English literature about autoimmune complications of HAV infection. We reported hematologic manifestations of HAV infection including hemophagocytic lymphohistiocytosis (HLH) and immune thrombocytopenic purpura as sole manifestations of HAV infection therefore in patients with these hematologic disorders, HAV infection should be kept in mind in the differential diagnosis even if they are not jaundiced.

Keywords: Hematologic manifestation, hepatitis A, child

Özet

Hepatit A virüs (HAV) enfeksiyonu çocukluk çağındaki genellikle asemptomatik ya da hafif seyirlidir, yaş artışında hastalığın ciddiyeti artar. Ekstrahepatik immün-aracılı bulgular ve hematolojik komplikasyonlar genellikle yetişkinlerde, akut ve kronik hepatit B ve C enfeksiyonlarının seryinde bildirilmiştir. Çocukluk çağında oldukça nadirdir. İngilizce literatürde, çocuklarda hepatit A'nın otoimmün komplikasyonlarını bildiren olgu sunumları oldukça azdır. Bu çalışmadan, immün trombositopenik purpura ve hemofagositik lenfohistiositoz (HLH) bulguları ile HAV tanısı alan iki çocuk olgu sunulmuştur, bu nedenle bu hastalıklarda tanı anında sarılık bulgusu olmasa da HAV enfeksiyonu akılda tutulmalıdır.

Anahtar Kelimeler: Hematolojik bulgu, hepatit A, çocuk

**Introduction**

Hepatitis A virus (HAV) infection in children is typically an acute, self-limited disease associated with general, nonspecific symptoms, such as fever, malaise, anorexia, and vomiting (1). In children younger than 5 years, HAV infection is usually inapparent; whereas, most adults present with symptoms, with the severity of the disease increasing with the age (1,2). Autoimmune complications such as idiopathic thrombocytopenic purpura (ITP), aplastic anemia, and hemophagocytic lymphohistiocytosis (HLH) have been rarely reported in children (3). Hepatitis A is a vaccine-preventable disease but it was not included in the national vaccination programme of Turkey before November 2012. Herein, we report hematologic manifestations associated with HAV infection in two pediatric patients without jaundice.

**Case Reports**

A Case 1 A previously healthy eleven year old boy admitted to our hospital with the complaints of bleeding in the mouth from oral mucosa, bruising all over the body, and petechial rash. Past history did not suggest an underlying liver disease or hematologic disorder. Several purpuric, petechial lesions and ecchymosis were detected on physical examination in his mouth, upper and lower extremities. His liver was 2 cm palpable, and spleen was not palpable. Physical examination of the other systems had normal findings. Laboratory investigations revealed elevated liver enzyme levels (AST 2512 U/L, ALT 2248 U/L), with the normal levels of alkaline phosphatase, total and direct bilirubin, gamma glutamyl transferase, ferritin, total protein, albumin, prothrombin time, activated partial thromboplastin time, fibrinogen and D-dimer. His white blood cell count was 2.26 x 10³/mL; hemoglobin 7.57 g/dL; hematocrit 21%; platelets 51 x 10³/mL. Coagulation studies revealed a prothrombin time of 13 seconds, active partial thromboplastin time of 29.5 seconds, a fibrinogen level of 130 mg/dL, and a dimer level over 4500 µ/mL. Blood chemistry revealed elevated liver enzyme levels (AST 546 U/L, ALT 587 U/L), C-reactive protein (13.6 mg/dL), lactate dehydrogenase enzyme (LDH) (2472 mg/dL), alkaline phosphatase (763 mg/dL), ferritin (16.600 µg/dL), and normal serum level levels of total and direct bilirubin, total protein and albumin, and blood urea nitrogen. Bone marrow aspiration showed hemophagocytosis. Hepatosplenomegaly was the main finding on ultrasonography. Her laboratory findings revealed pancytopenia, elevated triglyceride, and ferritin levels, hypofibrinogenemia, and hemophagocytosis in bone marrow aspiration, and these findings were fulfilled the diagnostic criteria of hemophagocytic lymphohistiocytosis (HLH). For the etiology, viral serologic studies were performed and found positive results for anti-HAV IgM and negative results for anti-HAV IgG, hepatitis B and C, Epstein-Barr virus, cytomegalovirus, toxoplasma, rubella, and parvovirus B19. He developed anti-HAV IgG, and serum anti-HAV IgM disappeared six weeks later. One month later after admission liver functions returned to normal levels. As a result of these findings, ITP as the sole manifestation of acute hepatitis A infection was diagnosed in our patient.

Case 2 A previously healthy 14-month girl referred to our hospital with prolonged fever, cough, loss of appetite, and malaise. Her physical examination revealed pallor, abdominal distension. The liver and spleen were both palpable 8 and 10 cm below the costal margin. She was not jaundiced and other system examinations had normal findings. She had a history of one sibling’s death and there was no consanguinity between her parents. There was no family history of immune or hematologic disorders. Peripheral blood counts showed pancytopenia (white blood cell 2.26 x 10³/mL; hemoglobin 7.57 g/dL; hematocrit 21%; platelets 51 x 10³/mL). Coagulation studies revealed a prothrombin time of 13 seconds, active partial thromboplastin time of 29.5 seconds, a fibrinogen level of 130 mg/dL, and a dimer level over 4500 µ/mL. Blood chemistry revealed elevated liver enzyme levels (AST 546 U/L, ALT 587 U/L), C-reactive protein (13.6 mg/dL), lactate dehydrogenase enzyme (LDH) (2472 mg/dL), alkaline phosphatase (763 mg/dL), ferritin (16.600 µg/dL), and normal serum level levels of total and direct bilirubin, total protein and albumin, and blood urea nitrogen. Bone marrow aspiration showed hemophagocytosis. Hepatosplenomegaly was the main finding on ultrasonography. Her laboratory findings revealed pancytopenia, elevated triglyceride, and ferritin levels, hypofibrinogenemia, and hemophagocytosis in bone marrow aspiration, and these findings were fulfilled the diagnostic criteria of hemophagocytic lymphohistiocytosis (HLH). For the etiology, viral serologic studies were performed and found positive results for anti-HAV IgM, and negative results for anti-HAV IgG, hepatitis B and C, Epstein-Barr virus, cytomegalovirus, toxoplasma, rubella, and parvovirus B19. Absence of the parental consanguinity and a known family history made the diagnosis of secondary HLH likely. Due to high endemicity in the South eastern region of Turkey and also her young age, we performed her genetic analysis and genetic defect was not detected in PRF1, SNX11, UNC13D genes for primary (familial) HLH. She was treated with steroid, and IVIG at a dose of 0.4 mg/kg/day was prescribed for 5 days. Ferritin level increased up to 15,900 µg/dL again, hypofibrinogenemia persisted (97 mg/dL), and her physical examination revealed hepatosplenomegaly. Her general condition did not improve despite steroid and IVIG therapy so we started cyclosporine. Her laboratory abnormalities improved dramatically after the onset of the cyclosporine. She was in good health at the 6th month of follow up.
**Discussion**

Hepatitis A infection is usually a self-limited disease conferring lifelong immunity (1-3). HAV infection associated with hematologic complications including severe aplastic anemia, virus-associated hemophagocytic syndrome (VAHS), postinfectious thrombocytopenic purpura, and immune thrombocytopenic purpura (4). Immune-mediated extrahepatic manifestations, and hematologic complications are mainly reported in adults with acute and chronic hepatitis B and C. However, they are relatively rare in children with hepatitis A (3,4). Thrombocytopenia may be a result of bone marrow depression, virus-associated hemophagocytic syndrome, immune-mediated peripheral destruction of platelets or increased platelet consumption associated with disseminated intravascular coagulopathy (3). We could find only seven pediatric patients with immune thrombocytopenia associated with HAV infection previously reported in English medical literature (3,5-10). Two of seven patients were not jaundiced on admission to the hospital, and our patient was the third (3-5). Ertem et al. (3) reported a 5-year-old girl whose initial manifestation was immune thrombocytopenia. Tanır et al. (9) reported a five year old boy with immune thrombocytopenia as the sole manifestation of HAV infection as our patient. In our patient we established the diagnosis with increased megakaryocytes in bone marrow aspiration suggested peripheral destruction of platelets, no hemophagocytosis in bone marrow and response to IVIG therapy. Immune thrombocytopenic purpura is usually a benign and self-limiting hematologic complication of HAV infection. Our patient had good response to IVIG therapy and thrombocytopenia resolved in seven days. HAV infection should be considered in the differential diagnosis of immune thrombocytopenic purpura in children without jaundice.

HLH and aplastic anemia are severe hematologic complications of HAV infections. Secondary HLH consists of a variety of conditions associated with infection, malignancy, autoimmune disorders, and drugs (11). Virus-induced HLH is a fatal disease and frequently complicates multiple organ failure or disseminated intravascular coagulopathy. The identification of an infectious organism does not help to discriminate between genetic and acquired forms of HLH, since also most episodes in genetic HLH are triggered by infections (12). In our patient we established the diagnosis of HLH with the HLA 2004 guideline, and we treated her with IVIG, steroid and cyclosporine. As a consequence of a history of one sibling’s death and high endemicity in that region of Turkey, we performed genetic analysis for primary HLH, but no genetic disorder was found. Bay et al. (13) described two previously healthy pediatric patients and our patient was the third, they responded to IVIG therapy, and hematological parameters turned to normal on third and fifth days. Our patient did not respond to IVIG and steroid therapy so the therapy switched to cyclosporine. Her hematological parameters turned to normal values at 12th day but triglyceride and ferritin levels which show activation, turned to normal levels after cyclosporine therapy onset.

Although many viral infections such as hepatitis B, parvovirus and Epstein-Barr virus are associated with extrahepatic autoimmune phenomena, such manifestations are rare during the course of acute HAV infection. Also extrahepatic complications are rare in children, serious complications may cost mortality and they serve as a source of infection for adults. The main manifestation of HAV infection on admission is jaundice, but these hematologic complications can initially manifest without jaundice; therefore, the patients presented with these hematologic disorders should be investigated for HAV infection.
